## 34 Abstract

35 **Backgrounds:** The emerging virus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has  
36 caused a large outbreak of novel coronavirus disease (COVID-19) in Wuhan, China since December 2019.  
37 Based on the publicly available surveillance data, we identified 21 transmission chains in Hong Kong and  
38 estimated the serial interval (SI) of COVID-19.

39 **Methods:** Index cases were identified and reported after symptoms onset, and contact tracing was conducted  
40 to collect the data of the associated secondary cases. An interval censored likelihood framework is adopted to  
41 fit a Gamma distribution function to govern the SI of COVID-19.

42 **Findings:** Assuming a Gamma distributed model, we estimated the mean of SI at 4.4 days (95% CI: 2.9–6.7)  
43 and SD of SI at 3.0 days (95% CI: 1.8–5.8) by using the information of all 21 transmission chains in Hong  
44 Kong.

45 **Conclusion:** The SI of COVID-19 may be shorter than the preliminary estimates in previous works. Given the  
46 likelihood that SI could be shorter than the incubation period, pre-symptomatic transmission may occur, and  
47 extra efforts on timely contact tracing and quarantine are recommended in combating the COVID-19 outbreak.

48 **Keywords:** novel coronavirus disease; serial interval; statistical analysis; Hong Kong; contact tracing.

49

## 50 Introduction

51 The novel coronavirus disease (COVID-19) is caused by the severe acute respiratory syndrome coronavirus 2  
52 (SARS-CoV-2, formerly known as the '2019-nCoV'), which has emerged in Wuhan, China in December 2019  
53 [1]. The COVID-19 cases were soon exported to other Chinese cities and overseas, and the travel-related risk  
54 of disease spreading was suggested by [2, 3]. Since the first confirmed imported case in Hong Kong on  
55 January 23, the local government has implemented a series of control and prevention measures for COVID-19,  
56 including enhanced border screening and traffic restrictions [4, 5].

57 As of February 15, there were 56 COVID-19 cases confirmed in Hong Kong [4], and local transmission was  
58 also recognized by the contact tracing investigation. Given the risk of human-to-human transmission, the  
59 serial interval (SI), which refers to the time interval from illness onset in a primary case (i.e., infector) to that  
60 in a secondary case (i.e., infectee) [6-9], was of interested to iterative rate of transmission generations of  
61 COVID-19. SI could be used to assist strategic decision-making of public health policies and construct  
62 analytical frameworks for studying the transmission dynamics of SARS-CoV-2.

63 In this study, we examined the publicly available materials released by the Centre for Health Protection (CHP)  
64 of Hong Kong. Adopting the case-ascertained design [10], we identified the transmission chain from index  
65 cases to secondary cases. We estimated the SI of COVID-19 based on 21 identified transmission chains from  
66 the surveillance data and contact tracing data in Hong Kong.

## 67 Data and methods

68 As of February 15, there were 56 confirmed COVID-19 cases in Hong Kong [4], which followed the case  
69 definition in official diagnostic protocol released by the World Health Organization (WHO) [11]. To identify  
70 the pairs of infector (i.e., index case) and infectee (i.e., secondary case), we scanned all news press released by  
71 the CHP of Hong Kong between January 16 and February 15, 2020 [5]. The exact symptoms onset dates of all  
72 individual patients were released by CHP [4], which were publicly available, and used to match each  
73 transmission chain. For those infectees associated with multiple infectors, we record the range of onset dates  
74 of all associated infectors, i.e., lower and upper bounds. We identified 21 transmission chains, including 12  
75 infectees matched with only one infector, that were used for SI estimation.

76 Following previous study [6], we adopted a Gamma distribution with mean  $\mu$  and standard deviation (SD)  $\sigma$ ,  
77 denoted by  $g(\cdot|\mu, \sigma)$ , to govern the distribution of SI. The interval censored likelihood, denoted by  $L$ , of SI  
78 estimates is defined in Eqn (1).

$$L(\mu, \sigma | \tau, T^{\text{low}}, T^{\text{up}}) = \prod_i \left[ \int_{T_i^{\text{low}}}^{T_i^{\text{up}}} h(t | T_i^{\text{low}}, T_i^{\text{up}}) g(\tau_i - t | \mu, \sigma) dt \right]. \quad (1)$$

79 The  $h(\cdot)$  was the probability density function (PDF) of exposure following a uniform distribution with a range  
80 from  $T^{\text{low}}$  to  $T^{\text{up}}$ . The terms  $T_i^{\text{low}}$  and  $T_i^{\text{up}}$  denoted the lower and upper bounds, respectively, for the range of  
81 onset dates of multiple infectors linked to the  $i$ -th infectee. Specially, for the infectees with only one infector,  
82  $T^{\text{low}} = T^{\text{up}}$ , and thus  $h(\cdot) = 1$ . The  $\tau_i$  was the observed onset date of the  $i$ -th infectee. We calculated the  
83 maximum likelihood estimates of  $\mu$  and  $\sigma$ . Their 95% confidence interval (95%CI) were calculated by using  
84 the profile likelihood estimation framework with cutoff threshold determined by a Chi-square quantile [12].

85 In the dataset, the latest onset date of all infectors was on January 31 in contrast to the investigation period up  
86 to February 15. Given the minimum investigation period at  $(15 - 0 + 1 =) 16$  days, which is approximately  
87 twice of the SI of the severe acute respiratory syndrome (SARS) [13], we ignored the right-truncated selection  
88 bias, i.e., 'infector-infectee' pairs with longer SI, due to short investigation period. Therefore, the likelihood  
89 framework defined in Eqn (1) was sufficient for the estimation in this study.

## 90 Results and discussion

91 The observed SIs of all 21 samples have a mean at 4.3 days, median at 4 days, interquartile range (IQR)  
92 between 2 and 5, and range from 1 to 13 days. For the 12 ‘infector- infectee’ pairs, the observed SIs have a  
93 mean at 3 days, median at 2 days, IQR between 2 and 4, and range from 1 to 8 days. Fig 1 shows the  
94 likelihood profiles of varying SI with respect to  $\mu$  and  $\sigma$  of SI. By using all 21 samples, we estimated the mean  
95 of SI at 4.4 days (95%CI: 2.9–6.7) and SD of SI at 3.0 days (95%CI: 1.8–5.8). The fitted Gamma distribution  
96 was shown in Fig 2. These estimates largely matched the results in the existing literatures [14, 15]. Limiting to  
97 only consider the 12 ‘infector-infectee’ pairs, we estimated the mean of SI at 3.1 days (95%CI: 2.0–5.4) and  
98 SD of SI at 1.8 days (95%CI: 1.0–4.7).

99 Comparing to the SI of SARS with mean at 8.4 days and SD at 3.4 days [13], the estimated 4.4-day SI for  
100 COVID-19 indicated rapid cycles of generation replacement in the transmission chain. Hence, highly efficient  
101 public health control measures, including contact tracing, isolation and screening, were strongly recommended  
102 to mitigate the epidemic size. The timely supply and delivery of healthcare resources, e.g., facemasks, alcohol  
103 sterilizer and manpower and equipment for treatment, were of required in response to the rapid growing  
104 incidences of COVID-19.

105 As also pointed out by two recent works [14, 15], the mean of SI at 4.4 days is notably smaller than the mean  
106 incubation period, roughly 5 days, estimated by many previous studies [16-19]. The pre-symptomatic  
107 transmission may occur when the SI is shorter than the incubation period. If isolation can be conducted  
108 immediately after the symptom onset, the pre-symptomatic transmission is likely to contribute to the most of  
109 SARS-CoV-2 infections. This situation has been recognized by a recent epidemiological investigation  
110 evidently [20], and implemented in the mechanistic modelling studies of COVID-19 epidemic [3, 21], where  
111 the pre-symptomatic cases were contagious. As such, merely isolating the symptomatic cases will lead to a  
112 considerable proportion of secondary cases, and thus contact tracing and immediately quarantine were crucial  
113 to reduce the risk of infection.

114 A recently epidemiological study used 5 ‘infector-infectee’ pairs from contact tracing data in Wuhan, China  
115 during the early outbreak to estimate the mean SI at 7.5 days (95%CI: 5.3–19.0) [17], which appeared larger  
116 than our SI estimate at 4.4 days. Although the 95% CIs of SI estimates in this study and [17] were not  
117 significantly separated, we note that the difference in SI might exist. If this difference was not due to sampling  
118 chance, one of the possible explanations could be the pathogenic heterogeneity in mainland China and Hong  
119 Kong. The SI estimate can be benefit from larger sample size, and the estimates in our study was backed up  
120 by 21 identified transmission chains including 12 ‘infector-infectee’ pairs, and thus it is likely to be more  
121 informative.

122 Accurate and consistent records on dates of illness onset were essential to the estimation of the SI. All samples  
123 used in this analysis were identified in Hong Kong and collected consistently from the CHP [4, 5]. Hence, the  
124 reporting criteria were most likely to be the same for all COVID-2019 cases, which potentially made our  
125 findings more robust.

126 The clusters of cases can occur by person-to-person transmission within the cluster, e.g.,

- 127 • scenario (I): person A infected B, C and D, or
- 128 • scenario (II): A to B to C to D, or
- 129 • scenario (III): a mixture of (I) and (II), e.g., A to B, B to C and D, or

130 or they can occur through a common exposure to an unrecognized source of infection, e.g.,

- 131 • scenario (IV): unknown person X infected A, B, C and D; or

- 132       • scenario (V): a mixture of (IV) and (I) or (II), e.g., X to A and B, B to C and D; or

133       The lack of information in the publicly available dataset made it difficult to disentangle such complicated  
134       situations. The scenarios (I) and (II) can be covered by the pair of ‘infector-infectee’ such that we could  
135       identify the link between two unique consecutive infections. Under the scenario (III), we cannot clearly  
136       identify the pairwise match between the infector and infectee, which means there were multiple candidate of  
137       infector for one infectee. As such, we employed the PDF  $h(\cdot)$  in Eqn (1) to account for the possible time of  
138       exposure ranging from  $T^{\text{low}}$  to  $T^{\text{up}}$ . There is no information available on the SI for scenarios (IV) as well as (V)  
139       due to the onset date of person X is unknown, and thus our analysis was limited in the scenarios (I)-(III). We  
140       note that extra-cautious should be needed to interpret the clusters of cases because of this potential limitation.  
141       Although we used interval censoring likelihood to deal with the multiple-infector matching issue, more  
142       detailed information of the exposure history and clue on ‘who acquires infection from whom’ (WAIFW)  
143       would improve our estimates.

144       Longer SI might be difficult to occur in reality due to the isolation of confirmed infections, or to identify and  
145       link together due to the less accurate information associated with memory error occurred in the backward  
146       contact tracing exercise. The issue associated with isolation could possibly bias the SI estimates and lead to an  
147       underestimated result. Due to lack of information in the public dataset, our estimation framework could be  
148       benefit from detailed records on the date of isolation of individual cases. But isolation occurs for all severe  
149       infectious diseases such as SARS and COVID-19, there is no reason to believe that isolation play a bigger role  
150       in one than the other, at least more evidence is needed to support that claim. It is however possible that at the  
151       initial stage the SI is longer than later when strict isolation takes place. Nevertheless, a comparison of  
152       estimated SI for SARS and COVID-19 in Hong Kong is still meaningful. And we found that the SI of  
153       COVID-19 estimated appears shorter than that of SARS, which is the key message. It would be hard to  
154       imagine that isolation is responsible for the difference. There is no reason to believe isolation is more rapid in  
155       cases of COVID-19 than in SARS in Hong Kong, as well as other limitations (would have happened for both).  
156       Thus, the difference we observed for COVID-19 and SARS is likely intrinsic. In conclusion, given the rapid  
157       spreading of the COVID-19, effective contact tracing and quarantine/isolation were even more crucial for  
158       successful control.

161 **Declarations**

162 **Ethics approval and consent to participate**

163 The follow-up data of individual patients were collected via public domain [4, 5], and thus neither ethical  
164 approval nor individual consent was not applicable.

165 **Availability of materials**

166 All data used in this work were publicly available via [4, 5], and the exacted dataset was attached as a  
167 supplementary files of this study.

168 **Consent for publication**

169 Not applicable.

170 **Funding**

171 DH was supported by General Research Fund (Grant Number 15205119) of the Research Grants Council  
172 (RGC) of Hong Kong, China. WW was supported by National Natural Science Foundation of China (Grant  
173 Number 61672013) and Huaian Key Laboratory for Infectious Diseases Control and Prevention (Grant  
174 Number HAP201704), Huaian, Jiangsu, China.

175 **Acknowledgements**

176 None.

177 **Disclaimer**

178 The funding agencies had no role in the design and conduct of the study; collection, management, analysis,  
179 and interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the  
180 manuscript for publication.

181 **Conflict of Interests**

182 The authors declared no competing interests.

183 **Authors' Contributions**

184 SZ conceived the study, carried out the analysis, and drafted the first manuscript. All authors discussed the  
185 results, critically read and revised the manuscript, and gave final approval for publication.
