APNet uncovers predictive drivers of COVID-19 severity

26 Abstract

27 Motivation: Computational analyses of plasma proteomics provide translational insights into complex 28 diseases such as COVID-19 by revealing molecules, cellular phenotypes, and signaling patterns that 29 contribute to unfavorable clinical outcomes. Current *in silico* approaches dovetail differential 30 expression, biostatistics, and machine learning, but often overlook nonlinear proteomic dynamics, like 31 post-translational modifications, and provide limited biological interpretability beyond feature ranking.

32 *Results:* We introduce APNet, a novel computational pipeline that combines differential activity 33 analysis based on SJARACNe co-expression networks with PASNet, a biologically-informed sparse 34 deep learning model to perform explainable predictions for COVID-19 severity. The APNet driver-35 pathway network ingests co-expression and classification weights to aid result interpretation and 36 hypothesis generation. APNet outperforms alternative models in patient classification across three 37 COVID-19 proteomic datasets, identifying predictive drivers and pathways, including some confirmed 38 in single-cell omics and highlighting under-explored biomarker circuitries in COVID-19.

Availability and Implementation: APNet's R, Python scripts and Cytoscape methodologies are

APNet uncovers predictive drivers of COVID-19 severity

74 1. Introduction

75 Human plasma is a vital clinical specimen encompassing a broad spectrum of proteins, including tissue 76 markers, immunoglobulins, transcription factors, kinases, metabolites, and secreted factors (Eldjarn et 77 al., 2023; Zhong et al., 2021). With the advent of high-throughput technologies (-omics), the human 78 plasma proteome has become a focal point for discovering novel biomarkers and therapeutic targets for 79 complex diseases. This has been especially the cases with severe COVID-19, a condition besetting 80 many patients infected with the SARS-CoV-2 coronavirus (Babačić et al., 2023). Plasma proteomics 81 have provided significant biological insights into the immunopathology of severe COVID-19, which is 82 characterized by the inflammatory "cytokine storm", Acute Respiratory Distress Syndrome (ARDS), 83 PANoptosis-induced cell death, and multiorgan failure (Diamond and Kanneganti, 2022). Plasma 84 proteomics has also been explored in long-COVID-19 syndromes and vaccine response variations 85 (Liang et al., 2023). 86 Many studies have measured plasma proteomics using Olink Proximity Extension Assay (PEA) in 87 COVID-19 research due to this technology's specificity, scalability and multiplexing benefits (Wik et 88 al., 2021). In our recent work, we assessed pertinent Machine Learning models applied in these high-

89 dimensional datasets like Random Forest, Gradient Boosted Decision Tree, XGBoost, Extra Tree 90 classifiers, Logistic regression, Lasso Logistic regression, Support Vector Machine (SVM), and Deep 91 Learning (DL) (e.g., AutoGluon-Tabular). Some models exhibited eXplainable AI (XAI) features by 92 deploying Shapley additive explanation (SHAP) values, the minimal-optimal variables method or a 93 random forest explainer. In the same work, we managed to dovetail an explainable, computational 94 pipeline to benchmark a wide assortment of ML tools on predicting COVID-19 severity from Olink 95 plasma proteomics which revealed Multi-Layer Perceptron (MLP) as the highest-performing algorithm 96 (Dimitsaki et al., 2023).

97 However, most of the above studies can partially approximate proteomic non-linear dynamics (e.g.,
98 post-translational modifications, protein co-expression networks, complex formation, and subcellular
99 localization), thus missing signaling proteins that may drive critical COVID-19 pathways. Moreover,
100 these studies' ML/DL findings often lack extensive external validation in large independent datasets,
101 while their biological explainability is usually restricted to mere feature ranking (Paul et al., 2023)
102 (Dimitsaki et al., 2023).

Acknowledging these challenges, we introduce Activity PASNet (APNet) in this manuscript. This computational DL pipeline initially uses the SJARACNe data-driven network algorithms to uncover disease drivers prioritized based on "activity," an aggregate metric of their capacity to regulate their transcriptional targets non-linearly (Ding et al., n.d.; Dong et al., 2023). These drivers can be overt (differentially expressed and possibly active) or "hidden" (differentially active but not expressed). Next, APNet feeds these drivers into Pathway-Associated Sparse Deep Neural Network (PASNet) (Hao et al., 2018), which incorporates biological priors as hidden layers to ultimately deliver interpretable

APNet uncovers predictive drivers of COVID-19 severity

clinical classifications, validated by the eXplainable AI component of SHAP values. Finally, APNet
facilitates the analysis of SJARACNe co-expression networks, equipped with the weights from the DL
classification task, to streamline data exploration and the formation of mechanistic hypotheses for
further biological investigation.

114 We extensively trained, tested, and validated APNet on activity matrices from 3 distinct Olink plasma

115 proteomic datasets (MGH, Mayo, Stanford) (Byeon et al., 2022; Feyaerts et al., 2022; Filbin et al.,

- 116 2021). APNet managed to pinpoint ground-truth drivers of severity, predicted new proteomic markers
- 117 with potential theranostic potential (some of which were traced to circulating PBMCs through scRNA-
- 118 seq analysis), outperformed alternative ML/DL models in demarcating severe COVID-19 cases and
- 119 enabled the inference of a potential signaling network from predictive factors in the liver of individuals
- 120 with severe COVID-19.
- 121

122 **2.** Materials and methods

123 2.1 APNet overview

APNet is a modular pipeline (Figure 1) which aims to facilitate the discovery of novel predictive driversof severe clinical outcomes and to facilitate the formulation of mechanistic hypotheses. In this present

- 126 work, we considered cases experiencing severe and non-severe COVID-19.
- 127

128 2.2 Brief description of APNet modular architecture

129 <u>2.2.1 Module 1- Differential activity analysis for drivers of COVID-19 severity</u>

130 In this module, conversions of expression values to activity values for plasma proteomics were 131 accomplished with NetBID2 (Dong et al., 2023) toolkit whereas for scRNA-seq data with scMINER 132 toolkit (Ding et al., 2023). For the plasma proteomics, we applied the NetBID2 algorithm, which 133 reverse-engineers context-specific interactomes and integrates network activity inferred from large-134 scale multi-omics data, empowering the identification of hidden drivers that traditional analyses cannot 135 detect. By leveraging the MSigDB database, we compiled distinct lists of Transcription Factors (TF) 136 and signaling molecule proteins. Separate TF and signaling molecule networks were constructed using 137 SJARACNe. These networks featured drivers (hubs) connected to their targets through protein-protein 138 interactions, derived from their expression patterns.

APNet uncovers predictive drivers of COVID-19 severity

To calculate the activities of driver proteins in each dataset based on protein expression, we employed
the "cal.Activity" function in NetBID2. The weighted mean activity of a driver candidate protein
(Driver{i}) in sample s, was computed using the following equation:

142
$$Driver_{si} = \frac{\sum_{j=1}^{n} SIGN_{ij} * MI_{ij} * EXP_{sj}}{n}$$

Here, the NPX count proteomics matrix, EXP{sj} represented the expression value of gene j in sample
s, MI{ij} indicated the mutual information between master regulator protein i and its target protein j,
and SIGN{ij} was the sign of the Spearman correlation between protein i and its target protein j. The
total number of targets for DRIVER i was denoted by n.

Differential activities were then computed for Severe and Non-Severe Status across the three datasets,
by using the "getDE.BID.2G" function, allowing us to identify genes exhibiting distinct regulatory
patterns in response to severity variations, through Bayesian model.

Also, we deployed the scMINER workflow, based also on SJARACNe, to discover severity drivers in
MGH scRNAseq data. For both differential expression and differential activity, the function get.DA
was performed by using the SCT matrix and activity matrix, respectively. Data visualisation for singlecell analysis was performed through the Seurat pipeline (4.3.0).

154 <u>2.2.2 Module 2- Driver-pathway mapping</u>

To prepare input data for the biologically explainable PASNet DL model on Module 3, joint differentially active drivers of severity from the three Olink studies were mapped to biological pathways using the Enrichr KG (Evangelista et al., 2023). 30 pathways from each of the following resources were leveraged (KEGG, Reactome, GO:BP and Wikipathways 2021) for the commonly decreased and increased drivers of severity separately. Drivers were mapped to the retrieved pathways in a binary fashion with 0s and 1s, i.e. when a driver was participating in the gene set of a pathway it was assigned the value of 1 and vice versa.

162 <u>2.2.3 Module 3-Deep Learning classification of Severe COVID-19 cases with biological</u> 163 <u>explainability</u>

The findings from Modules 1 and 2 served as input for Module 3, where a sparse neural network model called PASNet was used to predict COVID-19 severity. The model was trained on MGH data, validated on Mayo and tested on Mayo and Stanford datasets. A separate model was trained and tested using scMGH data. Model performance was evaluated using Area Under the Curve (AUC) and F1-scores,

APNet uncovers predictive drivers of COVID-19 severity

- along with ROC curve analysis. The PASNet training phase is expressed through the followingequations.
- 170 Sparsity of the PASNet sub-network function: $h^{(l+1)} = a((W^{(l)} * M^{(l)})h^{(l)} + b^{(l)})$

171
$$M^{(l)} = \{ I(|W^{(l)}| \ge Q^{(l)}), if \ l \ne 0 \}$$

$$M^{(l)} = \{A, if \ l = 0\}$$

- 173 where
- 174 $Q^{(l)}$ is the S-th percentile of $|W^{(l)}|$ if $l \neq 0$
- 175 M: mask matrix for each layer
- 176 *l*:layer
- 177 W: weight matrix
- b: vias vector

179 Cost-sensitive learning for imbalanced data: $L = \sum_{k=1}^{K} C_k + \frac{1}{2}\lambda ||W||_2$

180
$$C_k = \frac{l}{n_k} \sum_{i=1}^{n_k} c(y_i, \underline{y}_i)$$

181 Thus, the weights and biases on the *l*-th layer are updated by:

191
$$W^{(l)} \leftarrow (l - \eta \lambda) W^{(l)} - \eta \sum_{k=1}^{K} \frac{dC_k}{dW^{(l)}}$$

192
$$b^{(l)} \leftarrow b^{(l)} - \eta \sum_{k=l}^{K} \quad \frac{dC_k}{db^{(l)}}$$

- 182 where
- 183 C_k :mean error on the class k
- 184 y_i :ground truth
- 185 y_i :prediction
- 186 n_k :number of samples in the class k
- 187 *L*: total cost
- 188 c(.):cost function (e.g., cross-entropy loss)
- 189 λ : regularization hyperparameter
- 190 η :learning rate

APNet uncovers predictive drivers of COVID-19 severity

Biological explainability of the whole sparse DL model is predicated in the combination of Shapley
values (SHAP) and the driver-pathway mappings that PASNet architecture offers, assigning learning
weights.

196
$$\varphi_i = \sum_{S \in N \setminus \{i\}} \frac{|S|! (M - |S| - 1)!}{M!} [f(S \cup \{i\} - f(S))]$$

197 *N*: is the set of all input features

198 *i*: feature

199 *f*: model

200 *M*: is the number of features

201

202 <u>2.2.4 Module 4- Bipartite graph analysis</u>

203 This final APNet module leverages the SJARACNe co-expression networks from each study for the 204 joint differential active drivers and augments it by connecting drivers to pathways based on Module 2. 205 The weights of driver-driver edges contain the Mutual Information (MI) metric and the Spearman 206 correlation coefficient (positive values signify activation, negative values the opposite), amongst other 207 metrics. Driver-pathway edges contain as weights the PASNet-weights that PASNet learned during 208 training-testing tasks from Module 3. Our study used Cytoscape to perform network visualization, basic 209 analysis for network statistics and centrality metrics (Betweenness Centrality algorithm), 210 dimensionality reduction using tSNE (cluster signal propagation simulation (OCSANA+) and analysis 211 for shortest paths (PathLinker tool)(Gil et al., 2017; Marazzi et al., 2020).

212 OCSANA+ is a Cytoscape application that analyses the structure of large-scale complex networks. It 213 identifies nodes that drive the system towards a desired long-term behavior and ranks the combinations 214 of interventions that are likely to be more effective. Additionally, it estimates the effects of perturbations 215 in signaling networks. We used the Signal Flow Analysis (SFA) feature of OCSANA+ to simulate 216 signal propagation. The SFA algorithm estimates the signal flow in a signaling network by analyzing 217 the topological information. It employs a linear difference equation that considers a node's previous 218 activity, the effect and influence of incoming edges, and the initial activities of the node. The algorithm 219 focuses on the information conveyed by a series of biological interactions represented in a signaling 220 network (Marazzi et al., 2020).

PathLinker is a Cytoscape app based on an algorithm reconstructing interactions in a signaling pathway.
It requires a directed network, a set of sources, and a set of targets as inputs. The algorithm computes
the k best-scoring loopless paths and outputs the sub-network of the k best paths. The algorithm offers

APNet uncovers predictive drivers of COVID-19 severity

224 three choices for managing edge weights: (i) No weights: Path score is based solely on the number of 225 edges in the path, and PathLinker identifies the k paths with the lowest scores, (ii) Additive edge 226 weights: Path score results from the summation of edge weights, and PathLinker finds the k paths with 227 the lowest scores in this scenario as well, (iii) Probabilistic edge weights: Common in protein interaction 228 networks, where weight represents experimental reliability. PathLinker treats these weights as 229 multiplicative, seeking the k paths with the highest cost, where the product of edge weights determines 230 cost. Internally, PathLinker transforms each weight by taking the absolute value of its logarithm to map 231 the problem to the additive case (Gil et al., 2017) (Figure 2).

232

233 2.3 Technical benchmarking and bioinformatic validation based on COVID-19 prior knowledge

234 To benchmark APNet's performance on patient classification from Olink plasma proteomics, we 235 deployed the PASNet approach on original NPX values of Olink plasma proteomics and a Random 236 Forest model on the transformed activity values. Firstly, for PASNet we used the expression values for 237 training, validation and test, by using the count matrices of MGH, Mayo and Stanford, respectively. 238 The count matrices were filtered by keeping only the common significant proteins across 3 datasets 239 from Differential Expression analysis to perform the PASNet approach on expression data. Similarly to 240 the APNet approach, pathways collected from EnrichR-KG, by using (KEGG, Reactome, GO:BP and 241 Wikipathways 2021) for the commonly decreased and increased drivers of severity separately. PASNet 242 used the count matrices across 3 datasets for training, validation, and test, by using MGH, Mayo, and 243 Stanford respectively. Then for Random Forest, we used activity matrices from 3 datasets, by applying 244 training, validation and test into MGH, Mayo and Staford, respectively.

Bioinformatic validation of the top 20 most predictive drivers for each experiment was pursued by mapping these drivers to the 9 curated networks regarding COVID-19 immunopathological hallmarks

247 by SIGNOR (https://signor.uniroma2.it/covid/). Level 4 networks were obtained for each COVID-19

248 hallmarks and downstream processing was conducted in Cytoscape.

251

252 2.4 DOME recommendations

The assembly of APNet was performed considering the recently published DOME recommendations,a set of community-wide recommendations for reporting supervised machine learning–based analyses

Finally, selective data mining for key drivers of interest was performed in the web tool
 https://www.covid19dataportal.org/.

APNet uncovers predictive drivers of COVID-19 severity

applied to biological studies (see supplementary information) (Walsh et al., 2021) (SupplementaryMaterial 1).

257

258 **3. Results**

259 3.1 Harmonization of COVID-19 patient cohorts and assembly of plasma proteomic datasets

Initially, we harmonized patient stratification for COVID-19 severity based on WHOscore ("Severe" vs "NonSevere") across the three Olink proteomic datasets. In particular, COVID-19 cases who had a fatal outcome or were admitted in the ICU or were intubated were designated as "severe" and the residual cases were designated as "non-severe". In the MGH study, we designated 80 severe and 225 non-severe cases. In the Mayo study, we demarcated 268 severe and 181 non-severe COVID-19 cases. Furthermore, we determined 24 severe and 40 non-severe cases in the Stanford study. Associations with respective WHOscores and age can be seen in (Sup. Figure 1).

From all 3 Olink studies, 1463 common plasma proteins were bioinformatically studied within APNetand were used for downstream processing to uncover predictive markers of severity.

269

270 3.2 Data preprocessing and detection of severity drivers across proteomic studies

271 Next, we used the NetBID2 toolkit through APNet to detect common differentially active proteins 272 (DAPs) in severe COVID-19 cases, for all three Olink studies. Notably, for MGH, the prominent 273 positive drivers included TACSTD2, BAG3, POLR2F, DPY30, and CAPG. Conversely, the top 274 negative drivers for MGH were CCL22, BTC, IGFBP3, TNFSF11, and ICOSLG (Sup. Figure 2A). 275 Similarly, in the case of Mayo, the leading positive drivers consisted of VSIG4, IL1RL1, IL27, KRT19, 276 and JUN, while negative drivers entailed CDON, CD1C, ITGB7, TNFSF11, and LRRN1 (Sup. Figure 277 2B). For Stanford, the primary positive drivers were LGALS1, CSTB, MAD1L1, DDAH1, and CCL7 278 and the negative were EPCAM, CPA2, CDNF, DSG4, and CD1C. Pathway enrichment showed that 279 these severe COVID-19 top-drivers were associated with cell migration, monocyte activation, 280 methylation changes and immune cell dysregulation (Sup. Figure 2A-C).

From hereon, we focused on the commonly perturbed drivers across the three studies. APNet captured 333 common differentially active proteins (DAPs) across the three studies and encompassed 163 differentially expressed proteins (DEPs) and 170 hidden drivers (i.e., hidden in at least one of the three Olink datasets) (Figure 3A-B). Among the 333 common drivers, 150 were differentially hyper-active and 183 were hypo-active in severe COVID-19. When analyzing the STRINGdb network of common

APNet uncovers predictive drivers of COVID-19 severity

286 DAPs, centrality analysis prioritized DEPs like immuno-regulatory interleukins IL4-IL6, keratin 287 modulators (KRT19), chemokines for macrophages and neutrophils (CXCL8/CCL20) and transcription 288 factors (JUN). Other central decreased DEPs were effectors of T cell activation and proliferation 289 mediators of developmental pathways like the (CD8A, CD28), SCF/c-Kit pathway 290 (KIT/KITLG/IL7R/FLT3/CD34) and cellular adhesion surface molecules (ITGB1). Similarly, central 291 hyper-active hidden drivers ("positive") pertained to growth factors (HGF), ECM remodellers 292 (metalloprotease inhibitor TIMP1), chemoattractants of monocytes, natural killer and T-cells 293 (CXCL9/CXCL10/CCL3) and biomarkers of systemic organ failure (the lipocalin LCN2 indicating 294 acute kidney injury). Other central hypo-active hidden drivers included cellular adhesion molecules 295 (NCAM1, ITGB2, ITGAV), growth factors (FLT3LG, ligand for the FLT3 receptor found in DEPs) or 296 cognate receptors (EGFR, receptor for the Epidermal Growth Factor) and the tumour suppressor 297 molecule PTEN (Figure 3C).

298 Pathway enrichment through the Enrichr KG (KEGG, Wikipathways, Reactome, GO:BP) highlighted 299 several biological ground truths involved in COVID-19 immunopathology such as increased activation 300 of innate immunity, lung fibrosis, MAPK signaling, Sars-CoV-2 immuno-evasion, neutrophil 301 degranulation and viral protein interaction with cytokines and cognate receptors (Figure 3D). 302 Conversely, dwindling pathways in severe COVID-19 included the hematopoietic system, inhibitors of 303 the PI3K-Akt signaling pathway, cellular adhesion mechanisms through integrins and the Hippo-Merlin 304 signaling pathway, revealing an impairment of physiological proliferation and migration for circulating 305 immune cells (Figure 3E).

306 To better dissect the increased perturbational space captured by APNet, distinct cellular enrichment for 307 DEPs and hidden drivers was conducted using the GTEx Tissues database through Enrichr. DEPs 308 exhibited an over-representation for peripheral blood, spleen, liver, brain, and adipose tissue. Hidden 309 drivers, conversely, implicated other organs like oesophagus, tibial nerve and the cardio-vascular 310 system (Sup. Figure 3A-D). Ensuing pathway enrichment with WikiPathways and GO:BP uncovered 311 an expected affiliation of DEPs with key COVID-19 molecular "landmarks" like apoptosis, viral life 312 cycle, neutrophil degranulation, PI3K Akt signaling and impediments in synapse functionality and 313 angiogenesis. Interestingly, the hidden drivers were skewed towards aberrant insulin signaling, cellular 314 adhesion imbalances (L1cam interactions), propagation of hypoxia and abnormal neuronal behaviour 315 (increased neuroinflammation, decreased neuroplasticity) (Sup. Figure 3E-F, Sup. Figure 4).

These preliminary findings underline the importance of employing activity transformations on distinct COVID-19 plasma proteomic datasets using APNet. Beyond mere differential expression, this approach identified shared, systemic damages caused by Sars-CoV-2 across multiple organs and tissues (Supplementary Material 2-3).

APNet uncovers predictive drivers of COVID-19 severity

320 3.3 APNet classifies severe COVID-19 cases among distinct plasma proteomic studies

321 At this point, we hypothesized that the newly discovered hidden drivers had untapped biological 322 potential, which could enhance the clinical prediction of severe COVID-19 cases from plasma 323 proteomics.

324 We used the common DAPs across the three Olink studies for the ensuing clinical predictions. After 325 initial training in the MGH dataset (for details, see Materials and Methods), APNet accurately predicted 326 severe COVID-19 patients during the early testing phase (MGH-Mayo experiment) with significant 327 robustness (AUC = 0.96, F1 score = 0.9). Biological explainability highlighted the prognostic 328 significance of various DEPs (JUN, IL6, MAPK9, TNFRSF1A, AREG, NTF4, NCF2, TNFRSF10A, 329 FLT3, CKAP4, FLT3LG, SDC1, TNFRSF10B, TNFSF11) but also several hidden drivers (FTL3LG, 330 LYN, PTEN, EFNA1, ACAA1, HGF, TIMP1) (top-20). The most predictive pathways involved the 331 ground-truth "cytokine storm", MAPK signaling, vascular damage reflected on atherosclerosis 332 potential, protein folding (through HSP90 chaperone), and PI3K-Akt signaling pathway (Figure 4A-B).

During the second testing phase (MGH-Stanford experiment), APNet once again exhibited significant
predictive robustness since, on the Stanford dataset, it could foreshadow severe COVID-19 efficiently
(AUC = 0.91, F1 score = 0.68). Biological explainability revealed predictive drivers of severity, many
of which overlapped with the ones from the previous testing experiment (i.e. PTEN, JUN, IL6, LYN,
TNFRSF1A, TNFRSF10A, TNFRSF10B, TNFSF10) but also unveiled novel ones (BAX, LTA, KDR,
COL1A1, CCL7, EGFR, ERBB2, CCL22, PODXL, SEMA4D, KIT, ROBO1). The hidden drivers were
PTEN, BAX, CCL22, EGFR, LYN, ROBO1 (Figure 4C).

The most predictive pathways in this experiment involved viral infection and disruption of cytokines
and cognate receptors, PI3K-Akt signaling pathway, MAPK signaling, Hippo-Merlin signaling
dysregulation, and intensified Interleukin signaling pathway, apoptotic TRAIL signaling, neurotoxicity
concerning axonogenesis, and imbalances in lipid metabolism (Figure 4D) (Supplementary Material 4).

Hierarchical clustering on all cases across studies revealed associations of the most predictive drivers
with COVID-19 severity, while in the MGH study, further associations with diabetes and kidney disease
were also uncovered (Figure 4E).

347

348 3.4 APNet bridges plasma proteomics with single-cell transcriptomics

At this point, we decided to use APNet for a joint analysis between bulk plasma proteomics (MGH dataset) and scRNA-seq data from circulating peripheral blood mononuclear cells (PBMCs, 4 severe and 10 non-severe MGH cases). We sought to (a) prioritize which predictive drivers of COVID-19

APNet uncovers predictive drivers of COVID-19 severity

severity could be important for both -omic modalities and (b) trace the cellular origin of various
predictive drivers of COVID-19 severity from all the insofar classification experiments among the
PBMC cellular populations. (Figure 5A).

355 Initially, we deployed the scMINER toolkit to convert the typical sparse scRNA-seq expression matrix 356 into a non-sparse activity matrix based on the SJARACNe/MICA/MINIE algorithms (see Materials and 357 Methods for details). Single-cell differential activity analysis revealed 282 differentially active drivers 358 (140 DEGs and 142 hidden drivers) in severe COVID-19, which were also perturbed in the MGH 359 plasma proteomic analysis (Sup. Figure 5A). STRINGdb PPI network modeling and pathway 360 enrichment implicated several key COVID-19 severity drivers in innate/adaptive immunity, viral 361 replication, inflammatory signaling, cell adhesion and lipid metabolism (e.g., IL6, NCAM, LYN, PTEN, 362 ITGB1, ITGAM) (Sup. Figure 5B-D), in line with our findings from the previous plasma proteomic 363 analyses.

364 Next, we trained APNet on the MGH plasma proteomic dataset and tested it on the MGH single-cell 365 dataset (scMGH). APNet was highly robust in classifying severe COVID-19 cases (AUC: 0.99, F1-366 score: 0.975). The driver-pathway heatmaps pointed towards expected inflammatory and immune 367 pathways (e.g., IL18 signaling, TLR4 stimulation, T cell differentiation) as predictive signalling motifs 368 of severe COVID-19. Five predictive drivers from the previous plasma proteomic experiments were 369 found as predictive genes (MAPK9, TIMP1, JUN, IL6, TNFSF10). The other multi-omic predictive 370 drivers were S100A12, CD63, LAMP2, BIRC2, HMOX1, LGALS1, NFATC1, IL10RA, ATP6AP2, CD4, 371 ITGB1 (Figure 5B-C).

Lastly, we probed for the single-cell activity profile of various predictive drivers from the MGHMayo/MGH-Stanford/MGH-scMGH experiments. We discovered that the most active drivers in severe
cases were *JUN* (B/T cells) and *TIMP1* (all PBMCs except B cells and NKs). In contrast, in non-severe
cases, it was *PTEN* (monocytes and platelets) and *ACAA1* (all PBMCs but especially B cells). Like *ACAA1*, which opposed its proteomic counterpart, *CKAP4* was also increased in non-severe cases
(monocytes). Other active genes in all non-severe PBMCs were *FLT3LG*, *BAX*, *LYN* and *TNFSF10*,
while *NCF2* was mainly in severe monocytes (Figure 5D-E) (Supplementary Material 5).

Overall, these results elaborate on the cellular origins of certain predictive drivers for severe COVID19 inferred by APNet in PBMCs and were attained through APNet' noticeable versatility in bridging
across -omic modalities.

382

APNet uncovers predictive drivers of COVID-19 severity

383 3.5 Benchmarking APNet against alternative ML/DL methods

384 To benchmark APNet's significant performance on COVID-19 classification tasks, we initially 385 retrieved from the literature the predictive models published by the authors of the MGH study (Filbin 386 et al.), the Stanford study (Feyarts et al.), and of an independent study from Qatar which used the MGH 387 study for independent validation. As shown in Table 1, APNet outperformed the MGH and Stanford 388 models (Table 1). Although APNet showed similar performance to Oatar's predictive model (AUC > 389 0.95, training-testing on the authors' in-house data) in demarcating severe COVID-19 cases, it 390 outperformed Qatar's model in terms of generalizability. This was evident as the latter achieved an AUC 391 of 0.79 when independently tested on the MGH study (Table 1).

392

Study	AI model	AUC
Filbin et al. (MGH study)	Random Forest (elastic-net logistic regression with cross- validation)	0.85
Fayerts et al. (Stanford study)	(LASSO) linear regression	0.77 - 0.79 (Stanford study)
Al-Nesf et al. (Qatar study with Boruta algorithm)	MUVR	>0.959 (Qatar data) 0.76 (D0) (MGH validation)

393 Table 1. Published ML/DL analyzing MGH and Stanford Olink datasets

At this point, we performed more specific benchmarking experiments using (a) a variation of APNet where we provided only DEPs to the DL model instead of DAPs (PASNet-expression) and (b) an alternative variation where we substituted the PASNet architecture with one of the most widely used, explainable Machine Learning approaches like Random Forest (RF). The training, validation and testing datasets remained the same as before.

399 Noticeably, APNet outperformed all alternative DL/ML models based on activity or expression data 400 regarding AUC and F1-score (Figure 6A - B). More specifically, the PASNet-expression model 401 performed poorly on the Mayo dataset (AUC: 0.645, F1 score: 0.7475), and none of the predicted 402 molecules were hidden drivers. Biological explainability indicated ground-truth biological pathways 403 related to COVID-19 immunopathology were the most predictive pathways. However, some more

APNet uncovers predictive drivers of COVID-19 severity

404 nuanced pathways that APNet retrieved during the MGH-Mayo experiment were missing or under-405 represented (e.g., lipid imbalances) (Figure 6C-D).

The PASNet-expression model also under-performed in the Standford study compared to APNet, with an AUC of 0.89 and an F1-score of 0.54. Unsurprisingly, this expression-driven investigation in the Stanford study could only reveal a limited scope of predictive biological pathways like Cellular response to stress, positive regulation of intracellular signaling transduction, Neutrophil degradation, and viral protein response (Figure 6E-F).

411 The second alternative model based on Random Forest (RF) under-performed even more on Mayo and 412 Stanford datasets than the previous one since the models were validated with AUC: 0.65, F1-score: 413 0.4746, and AUC: 0.7375, F1-score: 0.6486, respectively, for each dataset. Noticeably, the top-414 predictive proteins were almost identical across the Mayo and Stanford datasets analysis. Concerning 415 the multi-omic experiment, we opted not to test the PASNet expression-driven model. This decision 416 was based on the intrinsic sparsity of the scRNA-seq data's expression and the apparent requirement for 417 specific data harmonization or more advanced ML/DL manipulations, which were beyond the scope of 418 our current project. Consequently, we exclusively employed the RF model on the shared perturbational 419 space identified through activity analysis between plasma proteomics and scRNA-seq data. This 420 approach underperformed compared to APNet, as evidenced by an AUC of 0.87 and an F1-score of 421 0.73 (Figure 6G).

With regards to associations with clinico-biological covariates, the most predictive proteins or drivers from the benchmarking studies exhibited correlations with COVID-19 severity but not to the extend that APNet's results did (e.g., this is evident in the expression-PASNet MGH-Mayo/Stanford and the RF MGH-Stanford experiments). Furthermore, associations with diabetes and kidney disease were not as straightforward as in the case of APNet (Supplementary Figure 6-7) (Supplementary Material 6).

427

428 **3.6** *In silico* evaluation of APNet's results based on COVID-19 curated prior knowledge

429 To evaluate the degree of COVID-19 ground truths that APNet and the other classification models 430 recovered, we mapped each model's top 20 most predictive proteins from the various experiments to 431 the SIGNOR 3.0 COVID-19 Hallmark pathways (i.e. Virus Entry, Cytokine storm, Inflammation, 432 Fibrosis, Apoptosis, Innate response to dsRNA, MAPK Activation, ER stress and Stress granules, 433 https://signor.uniroma2.it/covid/). APNet's most predictive drivers from the MGH-Mayo and the multi-434 omic experiments were considerably over-represented (1.5 to 2 fold) on the SIGNOR 3.0 COVID-19 435 Hallmark pathways than their counterparts from the PASNet-expression and RF models. Concerning 436 the MGH-Stanford experiment, APNet and PASNet-expression exhibited almost an equal number of

APNet uncovers predictive drivers of COVID-19 severity

- mappings but different in type, while the RF model was again significantly under-represented. In the
 case of MAPK activation, a cardinal pathway in COVID-19 pathobiology, APNet accomplished
 approximately twice as many mappings (8) as the expression-PASNet model (4), revealing higher
 robustness in connecting predictive drivers of severity with COVID-19 biological underpinnings (Table
 (Supplementary material 7).
- Table 2. Biological benchmarking of APNet vs PASNet Expression and RF-Activity. The table measures the number of
 top-20 predictive drivers that were mapped to the respective SIGNOR 3.0 pathway networks, in each classification experiment
 (SIGNOR 3.0 COVID-19 Hallmarks).

	MGH-Mayo			MGH-Stanford		scMGH		
SIGNOR 3.0 COVID-19 Hallmark	APNet	PASNet- Expression	RF-Activity	APNet	PASNet- Expression	RF-Activity	APNet	RF-Activity
Virus Entry	4	2	1	4	5	1	4	2
Cytokine Storm	5	5	0	5	7	0	7	3
Inflammation	6	5	0	9	7	0	7	2
Fibrosis	4	3	1	3	5	1	7	4
Apoptosis	9	5	1	8	7	1	5	2
Innate response to dsRNA	3	3	0	3	5	0	4	2
MAPK activation	6	3	1	8	5	1	6	3
ER stress	3	2	0	4	3	0	3	1
Stress granules	5	3	1	5	6	1	6	3
Total mappings	45	31	5	49	50	5	49	22

445

446

3.7 APNet enables the creation of weighted graph models for mechanistic hypotheses: The case ofACAA1

We postulated that combining SJARACNe co-expression networks, with pathways that APNet ingested
as biological priors before classification tasks and the weights it assigned to them upon completion of
demarcating severe COVID-19 could be helpful to *in silico* predict regulatory motifs and signaling
patterns driving severe COVID-19.

To demonstrate this feature, we focused on the MGH-Mayo experiment, we assembled a multipartite graph of with driver-driver and driver-pathway connections and we sought to leverage information

APNet uncovers predictive drivers of COVID-19 severity

about ACAA1 (Acetyl-CoA Acyltransferase 1), which was one of the top 20 most predictive drivers,

- 456 was designated as a hidden driver by our analysis and it was significantly hypo-active in severe PBMCs
 - 457 which suggested the its plasma proteomic signature derived from an alternative tissue or organ.

By retrieving the MGH SJARACNe SHAP graph (a series of small positive, coherent feedforward loops with NCF2, TIMP1, CKAP4 as sources, TNFRSF10B as a significant "sink" and FLT3 as the primary inhibitor), it was apparent that no obvious connection existed between ACAA1 and the other predictive drivers (Figure 7A). To validate the biological plausibility of the SJARACNe graph, the respective PPI network from STRINGdb was leveraged (interaction score > 0.4), indicating high interconnectivity for most of the predictive drivers. Interestingly, ACAA1 and CKAP4 remained unconnected

464 (https://version-12-0.string-db.org/cgi/network?networkId=bmlgZrzN1Cex) (Figure 7B).

465 Next, considering that ACAA1 is predominantly expressed in the liver based on our previous GTEx 466 analysis, we took inspiration from representation learning (Zitnik et al., 2019) and performed 467 dimensionality reduction on the APNet complex graph with the tSNE algorithm, looking for maximum 468 variance in liver expression based on TISSUES 2.0 scores. A distinct cluster with highly liver-specific 469 drivers was detected. To gain a better insight on them, we isolated their subgraph with their most 470 prognostic connected pathways (PASNet weight > 0.5 and < -0.5). We detected a graph "island" which 471 contained four highly predictive drivers of COVID-19 severity among other proteins (ACAA1, SDC1, 472 HGF, CKAP4) and connected pathways involved Immune System signaling, neutrophil degranulation,

473 MAPK signaling, chaperone activation (HSP90) and VEGF signaling (Figure 7C-D).

Based on these findings, we posited that there should be an underlying connection between ACAA1
and some of the other three predictive drivers of severity. We resorted to the OCSANA+ Cytoscape
application to simulate signal propagation from SDC1, HGF and CKAP4 on the APNet complex graph.
By calculating the Signal Flow Analysis (SFA, see Materials and Methods) metric, it became apparent
that HGF and SDC1 signal propagation converged towards ACAA1 through various intermediate
proteins. A similar effect on ACAA1 was not observed in the case of CKAP4, which did not appear to
propagate any signal towards ACAA1 (Figure 7E).

481 To better elucidate these findings, we calculated the shortest paths from SDC1, HGF and CKAP4 482 towards ACAA1 using the PathwayLinker application on Cytoscape. When selecting the "additive 483 weight method" for the MI score as edge weight, PathLinker highlighted 2 critical shortest paths: (a) a 484 signaling cascade commencing from SDC1 and reaching ACAA1 through KRT18 and GRPEL1 and 485 (b) an incoherent feed-forward loop starting from HGF and through inhibiting ICOSLG which activated 486 PTPRS which inhibited ACAA1. The "unweighted method" in PathwayLinker returned the same 487 results. Notwithstanding, when selecting the "probabilistic weight method" for the MI score as edge

APNet uncovers predictive drivers of COVID-19 severity

weight, PathwayLinker suggested a larger signaling cascade commencing from CKAP4, and extendingthrough TRIAP1, LBR and GRPEL1 towards ACAA1 (Figure 7F).

490 To computationally validate these APNet shortest paths, we queried the STRINGdb database for the 491 respective PPI networks. After 2 rounds of expansion, we retrieved a singular PPI network (14 nodes, 492 23 edges, https://version-12-0.string-db.org/cgi/network?networkId=b57tJ84II6T8), connecting SDC1, 493 GRPEL1, KRT18 and ACAA1 which upon k-means clustering revealed three components relative to 494 fatty-acid metabolism (ACAA1, ACOX1, HADHA, HSD17B4, EHHADH), mitochondrial protein 495 transport (HSPA9, KRT18, KRT8, GRPEL1, TIMM44) and cell surface interactions (FN1, SDC1, 496 SDCBP, FGF2). In the case of the other shortest paths, the corresponding STRINGdb queries required 497 more than 5 cycles of expansion to produce PPI networks encompassing all drivers of interest (CKAP4: 498 55 nodes, 375 edges, https://version-12-0.string-db.org/cgi/network?networkId=bjbqEWsYzPw4; 499 HGF: 44 nodes, 214 edges, https://version-12-0.string-db.org/cgi/network?networkId=bcT9lsyOCwJ7) 500 (Sup. Figure 8).

- 501 Finally, as an additional step to assess the potential significance of these paths in a more COVID-19-502 specific biological queried the BYCOVID19 context, we data portal 503 (https://www.covid19dataportal.org/) for the "COVID-19 association score" provided by the 504 OpenTargets platform. SDC1 exhibited the highest score (0.555) with a considerable difference from 505 some of the other drivers of severity (KRT18=0.05, LBR=0.004, CKAP4=0.006, HGF=0.025), 506 confirming the biological prioritization of the SDC1-ACAA1 nascent connection that APNet uncovered 507 (Supplementary Material 8-9).
- 508

509 4. Discussion - Conclusion

In the current work, focusing on COVID-19 omics, we present APNet, a computational DL pipeline to
elucidate complex biological motifs while classifying patients based on their clinical severity.

512 APNet is inspired by computational approaches modeling Gene Regulatory Networks (GRNs), which 513 have been instrumental in discovering new interactions between biological entities and formulating 514 novel scientific hypotheses. APNet combines some of the best practices in the field by combining an 515 Information Theory model (SJARACNe algorithm) through a Bayesian scope (NetBID2/scMINER 516 toolkits) (Delgado and Gómez-Vela, 2019) and a biologically-informed neural network with enhanced 517 explainability (PASNet and SHAP values) for supervised patient clustering. The above bioinformatic 518 tools have been shown independently to effectively discover potential biomarkers and druggable targets 519 in diseases however, to the best of our knowledge, they have never been used as a unified pipeline for 520 COVID-19 or any other disease type (Wang et al., 2021) (Ding et al., 2023) (Hao et al., 2018).

APNet uncovers predictive drivers of COVID-19 severity

521 In our study, we utilized APNet to predict severe COVID-19 cases in three different Olink plasma 522 proteomic datasets (MGH, Mayo, Stanford), and a complementary scRNA-seq study. APNet conducted 523 biologically informed predictions using driver-pathway associations (KEGG, Reactome, GO:BP, 524 Wikipathways) with remarkable robustness, outperforming alternative ML/DL approaches which either 525 lacked (a) the activity transformations enabled by the NetBID2/scMINER toolkits (PASNet-expression 526 model) or (b) the PASNet DL architecture (Random Forest classifications). Based on the biological 527 explainability of each model (SHAP values, driver-pathway mapping with learning DL weights) and 528 COVID-19 curated biological ground-truths (SINGOR COVID-19 pathway networks), evidently, 529 APNet was able to better approximate the systemic nature of severe COVID-19 from the provided 530 biological data. We posit that APNet performed so efficiently due to the sparse regularization of the 531 hierarchical relationships of drivers and pathways after initial differential activity analysis. Hence, 532 APNet was able to capture both well known but also more nuanced perturbations in severe COVID-19 533 (i.e., known drivers but also "hidden drivers" like ACAA1, FLT3) implicating several potential tissues 534 of origin and a diverse repertoire of critical pathways. Indicatively, some of the most predictive drivers 535 and pathways that APNet captured concerned apoptosis, dishevelled PI3K-Akt stimulation 536 (FLT3/FLT3LG, PTEN, NTF4, KIT), neurodegeneration (EGFR, SEMAD4), cell differentiation 537 (TNFSF11), neutrophil degranulation (ACAA1), lipid metabolism (TNFRSF10A), immune and 538 interleukin signaling (CD63, TIMP1, JUN), T cell receptor signaling (BIRC2, NFATC1, CD4, 539 IKBKG), oxidative phosphorylation (ATP6AP2). These signaling cascades and some of these drivers 540 have already been implicated with COVID-19, which attests to APNet's overall capacity to make 541 biologically plausible predictions. (Basile et al., 2022; Chidambaram et al., 2022; Merad and Martin, 542 2020; Pistollato et al., 2022; Thompson et al., 2021). A paradigmatic case concerning the translational 543 value of APNet's findings was the implication of MAPK pathway in severe COVID-19 based on various 544 drivers (e.g., MAPK9, AREG, KIT, JUN, FLT3LG). These drivers were not prioritized to the same 545 extend as highly predictive by the alternative ML/DL models – if prioritized at all. This could explain 546 in part why APNet surpassed these models as a classifier of COVID-19 severity since components of 547 the MAPK pathway (sH-RAS, C-RAF, MAPK1, MAPK2 and ERK) have emerged as critical tenets of 548 Sars-CoV-2 tropism in PBMCs and have been associated with adverse clinical covariates like hypoxia, 549 dyspnoea and vascular damages (Cusato et al., 2023).

Finally, APNet extends beyond biological explainability to actionability regarding the formulation of mechanistic hypotheses, by providing the capacity to generate a weighted driver-pathway network that incorporates information from SJARACNe co-expression networks, the differential activity analysis, the PASNet DL clinical predictions and external dedicated bioinformatic databases like STRINGdb. APNet enabled through graph representation learning, shortest path detection, and signal propagation simulation the prediction of a liver-specific signaling cascade in severe COVID-19 involving ACAA1 (*hidden driver with prognostic significance but no apparent connections to other predictive drivers*),

APNet uncovers predictive drivers of COVID-19 severity

SDC1, KRT18, and GRPEL1. These predictions are not biologically implausible given the implication
of SDC1 and KRT18 in inflammation and epithelial damage (Ghondaghsaz et al., 2023; Liao et al.,
2020), the involvement of the mitochondrial GRPEL1 in host/Sars-CoV-2 interactions (Zhang et al.,
2022), the clinical correlation of ACAA1 (a mediator of fatty acid oxidation in the mitochondria and
the peroxisomes) with ICU-admittance in COVID-19 (Penrice-Randal et al., 2022) and a severe
mitochondria dysfunction in the liver of severe COVID-19 cases (Guarnieri et al., 2023).

- 563 The work herein is not without its limitations. One limitation concerns the restricted number of studies 564 involved and the binary assignment of drivers to pathways. Pathway activation is a dynamic process 565 controlled by fluctuations in expression or activity changes of a protein or drivers, respectively. Outputs 566 from more advanced pathway enrichment techniques like GSEA could be more instructive for the DL 567 model to perform classifications more aptly. Another limitation is the need to perform several manual 568 steps in APNet's complex graphs to test hypotheses and leverage new insights, which might hinder data 569 exploration and analysis. Another issue worth noting is that APNet does not include clinical covariates 570 as clinical-biological priors, which could be addressed in the future by adopting in our pipeline the more
- 571 clinically-oriented version of Cox-PASNet (Hao et al., 2019).

572 Overall, APNet is a robust pipeline that can simplify the extraction of intricate biological insights from 573 complex biological data while also performing clinical predictions and testing mechanistic hypotheses. 574 *In vitro/in vivo* validations should accompany future implementations of APNet to validate the 575 pipeline's true translational credibility. Additionally, APNet's scalability to other multi-factorial 576 disease-omic datasets (such as cancer and neurodegenerative diseases) should be explored along with 577 its potential deployment in other computational tasks (like multi-omic data integration and interactions 578 with knowledge graph pipelines).

APNet uncovers predictive drivers of COVID-19 severity

794

Figure 1. APNet workflow, as implemented in the herein COVID-19 multi-omic study to discover predictive drivers ofseverity. Image made using the Biorender toolkit.

- 797
- 798

801 connections among drivers and pathways.

802

803

Figure 3. APNet uncovers a large COVID-19 perturbational proteomic space underpinning the 3 distinct Olink datasets (MGH, Mayo, Stanford). (A) Venn diagrams showing overlapping differentially expressed proteins (DEPs) and differentially active proteins (DAGs) among the three studies. (B) SuperVenn diagram depicting the joint differentially expressed (increased/decreased) or active proteins (hyper/hypo-active) in severe COVID-19 compared to non-severe COVID-19 cases, across the three Olink studies. (C) STRINGdb protein-protein interaction networks for joint DEPs and hidden drivers of severity across the three studies (STRINGdb score > 0.4). The size of the nodes is analogous to the centrality of each protein/driver (BetweenessCentrality algorithm) and the colour denotes perturbational direction (red for increased, blue for decreased). (D-E) Bubble plots depicting over-representation analysis based on the Enrichr Knowledge Graph (Wikipathways 2021, Reactome, GO:BP, KEGG) for joint drivers with increased (D) and decreased activity (E) in severe COVID-19 cases, among the three Olink plasma proteomic studies.

Figure 4. APNet deploys sparse regularization of driver-pathway connections through the PASNet Deep Learning model and robustly classifies severe from non-severe COVID-19 cases in the three Olink proteomic studies. (A-B) Bar plots for SHAP values and driver-pathway mapping from PASNet signifying the top-20 predictive drivers and their corresponding pathways, for the MGH (training) / Mayo (testing) experiment. Furthermore, the AUC and F1-score values are depicted. (C-D) Same as (A) for the MGH (training) / Stanford (testing) experiment. Class 0 refers to nonsevere and Class 1 refers to severe COVID-19 cases. (E) Hierarchical clustering of MGH, Mayo and Stanford cases on the basis on the predictive proteomic drivers, along with selected clinical covariates.

APNet uncovers predictive drivers of COVID-19 severity

Figure 5. APNet classifies severe COVID-19 cases across multi-omic studies. (A) scRNA-seq data from the Villani group for 14 MGH cases. (B-C) Bar plots for SHAP values and driver-pathway mapping from PASNet signifying the top-20 predictive drivers and their corresponding pathways, for the MGH plasma proteomic (training) / scRNA-seq (testing) experiment. Furthermore, the AUC and F1-score values are depicted. Class 0 refers to nonsevere and Class 1 refers to severe COVID-19 cases. (D-E) Heatmaps depicting the activity and the expression of predictive drivers from all the APNet experiments, across various PBMC cell types. The scMINER toolkit and visualisation performed the activity calculations were attained through Seurat. Only the predictive drivers with positive activity values are depicted.

Figure 6. APNet outperforms alternative ML/DL models in classifying severe and non-severe COVID-19 cases. (A) ROC curves depicting the performance of APNet and alternative approaches in classifying severe from non-severe cases in respective experiments. Distinct AUC scores are referenced also. (B) Lollipop plot depicting the F1-scores from each model from (A). **(C-F)** Barplots with SHAP values for the top 20 most predictive plasma proteins of COVID-19 severity and protein-pathway mapping from PASNet-expression model for MGH-Mayo experiment (C-D) and MGH-Stanford experiment (E-F). (G) Barplots with SHAP values showing top 20 most predictive drivers of severity based on the Random Forest (RF) alternative model for the various classification experiments. Class 0 refers to non-severe and Class 1 refers to severe COVID-19 cases.

Figure 7. APNet enables the assembly of complex graphs that can be leveraged to discover non-apparent connections of ACAA1 with other predictive drivers of COVID-19 severity. (A) SJARACNe co-expression (adj.pvalue<0.05 for MI calculation) directed network from APNet's complex graph showing the interactions of the top 20 most predictive drivers of COVID-19 severity for the MGH-Mayo scenario. (B) STRINGdb network with (interaction score > 0.4) for the same severity drivers. **(C)** APNet's complex graph after tSNE dimensionality reduction using the clusterMaker app in Cytoscape, based on the "liver" score from the TISSUES 2.0 database for each driver/node. The darkest colour denotes a higher liver-specific association. The most liver-specific cluster of drivers is designated within the circle (continue to next page...)

APNet uncovers predictive drivers of COVID-19 severity

810 Figure 7. APNet enables the assembly of complex graphs that can be leveraged to discover non-apparent connections of ACAA1 with other predictive drivers of COVID-19 severity (continued..) (D) Part of APNet's complex graph showing highly liver-specific drivers and connected pathways with high prognostic significance, based on their PASNet weights. (E) Lollipop plots showing the SFA scores from the OCSANA+ app in Cytoscape in each node, after signal propagation from SDC1, CKAP4 and HGF on the entire APNet complex graph. (F) Part of APNet's complex graph showing shortest paths based on the PathLinker app in Cytoscape starting from CKAP4, SDC1 and HGF and extending towards ACAA1. Below, the STRINGdb equivalent PPI network (interaction score > 0.4) of the SDC1-KRT18-GRPEL1-ACAA1 path with intermediate nodes provided by STRINGdb, after k-means clustering.
