

24 **ABSTRACT (204 words)**

25 **Background**

26 The SARS-CoV-2 virus has caused a global health crisis, resulting in a significant
27 loss of human lives. It is essential to report disease and mutation associations to
28 provide ideas for public health interventions and preventive measures.

29 **Methods**

30 In this study, to determine the association between genomic variants and the
31 severity of pneumonia caused by SARS-CoV-2, a sequencing analysis of 150
32 patient samples with confirmed COVID-19 was conducted. These samples were
33 collected between 2021 and 2023 and isolated in Aguascalientes, Mexico.

34 **Results**

35 The patient cohort had males and females ranging from 0 to 91 years old. Males
36 accounted for 66% of the population analyzed. The Delta variant was the most
37 prevalent lineage associated with deaths in 2021-2022, while the B.1.1.529
38 lineages emerged in mid-2022. Currently, the XBB lineage is the most commonly
39 identified in Mexico. New mutations L95M and L46M in ORF 8 and ORF 9 were
40 discovered in 30% and 20% of the sequences and are uniquely present in the
41 studied population. These mutations are positively associated with patient death.

42 **Conclusions**

43 This study provides valuable data to aid in understanding the evolution of SARS-
44 CoV-2 in specific populations and explores the severity of the disease and
45 mutation correlations.

49 **INTRODUCTION**

50 At the end of 2019, a new coronavirus emerged in Wuhan, China. Initially, it was
51 identified as WH-Human 1 coronavirus (WCHV). It exhibited genomic similarity of
52 79.8% related to SARS-CoV and 59.1% associated with MERS-CoV, as well as
53 showing 100% amino acid similarity in the E and nsp7 with bat SL-CoVZC45
54 proteins, all possibly derived from recombination events [Wu et al., 2020]. SARS-
55 CoV was determined to have high homologous similarity to CoV bat virus RmYN02
56 in most of its genome but shows weak homology in the receptor binding domain
57 (RBD) that makes up the S1 subunit of the spicule (S) protein, which represents a
58 critical factor in host receptor recognition and the process of cell membrane fusion
59 with angiotensin-converting enzyme 2 (ACE2). The tissue ubiquity of the latter
60 explains the multiple manifestations and affectations of the disease [Ren et al.,
61 2020].

62 Coronaviruses, members of the Orthocoronaviridae family within the Coronaviridae
63 domain, are enveloped viruses with a single-stranded positive RNA genome
64 (approximately 26 to 32 kb in length). They are classified into four genera:
65 Alphacoronaviruses (□), Betacoronaviruses (□), Gammacoronaviruses (□), and
66 Deltacoronaviruses (□). The viral genome typically encodes four structural
67 proteins: Spike (s), envelope (E), membrane (M), and nucleocapsid (N), along with
68 numerous non-structural proteins and multiple accessory proteins [Ren et al.,
69 2020].

70 Now recognized as Severe acute respiratory coronavirus 2 (SARS-CoV-2), it is a
71 highly contagious virus that caused the COVID-19 pandemic disease that brought
72 the world to a standstill, with a primary reproduction number (R_0), which depends
73 on several factors, including the circulating variant, therefore, for Delta the R_0 was
74 3.2 and for Omicron it was 9.5, which also depends on the population density, the
75 mobility patterns, social interactions, and vaccination policies (Roy S, et al, 2023).
76 It is a single-stranded positive RNA virus with a length of 29,891 nucleotides,
77 encoding 9,860 amino acids. Its genome comprises 14 open reading frames
78 (ORFs) and 27 proteins, of which the structural proteins are spike (S), envelope
79 protein (E), membrane protein (M), and nucleocapsid (N) (Chan et al., 2020). As of
80 December 2023, there have been 772 million confirmed cases of SARS-CoV-2
81 worldwide and 6.9 million deaths attributed to the disease. In Mexico, the first case
82 of COVID-19 was detected on February 27, 2020, and as of today, there are 7.7
83 million confirmed cases and 334,917 deaths [WHO, 2023; Garcés-Ayala et al.,
84 2020]. The pandemic propelled advancements in molecular biology techniques
85 that allowed us to answer crucial questions, particularly the Delta and Omicron
86 variants. It clarified everything related to the development of the disease, such as
87 the relationship between the characteristics presented and the risk of death or
88 infection susceptibility in prolonged-stay settings [Anderegg et al., 2023; Iqbal et
89 al., 2023].

90 Epidemiological surveillance has proven indispensable in identifying mutations that
91 affect the virus's behavior, enhancing its infectious capacity, or evading the
92 immune system.

93 It has been reported that Latin American countries have experienced an increase
94 in the frequency of virus mutation, with a particular prevalence in these countries
95 compared to other regions. This geographical area could be the origin of new and
96 potentially dangerous virus variants that could later spread globally. This report
97 only covers the period of 2021-2022 [Dhruv Yadav et al. 2022].

98 In the first year of the pandemic in Mexico, numerous lineages were detected,
99 some transient. In contrast, others, such as B.1, B.1.1.1, and B.1.1.519, among
100 others, represented up to 76% of the circulating lineages in Mexico during this first
101 year, in addition to exhibiting the mutations P314L in protein nsp12 and D614G in
102 spike protein with a prevalence of 99% and 98 % respectively [Taboada et al.,
103 2021]. The spike protein has been a focal point of numeral studies, given its high
104 mutation rate, which gives it the ability to have immune escape. This capability
105 allows the virus to infect even vaccinated or previously infected individuals [Harvey
106 et al., 2021].

107 After the first year of the pandemic, the Delta variant, with AY20 and AY.26
108 lineages, replaced other variants and marked the third wave. Finally, the Omicron
109 variant and its respective lineages entered in December 2021, initiating the fourth
110 wave becoming the variant with the highest daily case count. This variant and the
111 recombinant XBB sublineage have spread even among vaccinated populations
112 [García-López et al., 2022]. It is unclear whether the reported regional mutations
113 are related to the alarming case-fatality rates in Mexico. Before vaccination, the
114 rate was 10%, but it has dropped to 4,5% in 2024. These rates are higher than the
115 worldwide average (John Hopkins University, 2024).

116 Therefore, this project aims to determine the genomic sequence of SARS-Cov2 in
117 samples detected by quantitative reverse transcription polymerase chain reaction
118 (RT-qPCR) in central Mexico from patients with severe respiratory infection to
119 establish a possible association between the severity of pneumonia, death
120 incidence, and genomics variants.

121 **METHODS**

122 Clinical data were collected from 300 biosamples from deaths in the state of
123 Aguascalientes who tested positive for COVID-19, confirmed by RT-qPCR,
124 spanning from August 2021 to May 2023. The clinical information includes
125 demographic data (age, gender, and vaccination status), comorbidity details,
126 symptoms, and their duration until death (Table 1). Samples with CT values of 28
127 or less were selected for sequencing using the Illumina CovidSeq protocol
128 following the manufacturer's instructions and utilizing the Illumina MiniSeq
129 Sequencing System. In total, 173 samples were subjected to sequencing.

130 The obtained FASTQs from the sequencing process were assembled using CLC
131 Genomics Workbench software, with Wuhan-Hu 1 (NC_045512.2) as the reference
132 genome. Subsequently, the Genome Annotation of the BV-BRC platform
133 (<https://www.bv-brc.org/app/Annotation>) was used to visualize the general genome
134 structure. Based on the quality of each genome, nucleotide contents were
135 analyzed, and those containing 10% or more Ns quantity were excluded from the
136 study. Finally, 150 good-quality sequences were selected for analysis and

137 uploaded to the GISAID platform (<https://gisaid.org/>) for consultation. Sequence
138 identifiers are stated in Table 2.

139 Following the PANGO designation (https://cov-lineages.org/lineage_list.html), the
140 lineage data were interpreted as delta and omicron variants for further analysis.
141 Frequency and percentages were calculated for all the subject characteristics. The
142 mean (\pm SD) was calculated for the age and duration of the symptoms until death.
143 The normality of data was assessed using the Shapiro-Wilk test. The p-value was
144 calculated through the chi-square test for categorical variables, comparing the
145 presence and absence of each comorbidity and symptom and the male or female
146 gender. Mann - Whitney test was used for non-parametric data comparing the ages
147 of the subjects infected with the delta or omicron variant and the duration of the
148 symptoms until death between the two variants.

149 Multiple sequence alignments were generated using the online program Multiple
150 Sequence Alignment and SNP / Variation Analysis at the BV-BRC platform
151 (<https://www.bv-brc.org/app/MSA>) for the different structural and non-structural
152 proteins in different groups and as a whole. The representative genomes of the B,
153 B.1.1.529, BA.1, B.1.351, B.1.617, B.1.1.7, B.1.429, and XBB lineages were used
154 for alignments, using Wuhan-Hu 1 as the reference genome. In the same way, a
155 control group of 443 genomes of the circulating lineages in Aguascalientes
156 between 2021 to 2023 was generated. The genomes selected for the control group
157 are of the period mentioned and at least one sequence of each state of Mexico
158 was introduced.

159 The alignments were carefully inspected to identify mutations with at least 45%
160 prevalence among the total analyzed sequences. These selected mutations
161 provided an overview of circulating mutations in the center of México between
162 2021 and 2023. A matrix was made considering the absence and presence of the
163 mutation in each sequence. Using R programming language, a heat map was
164 generated to represent the presence of mutations in each sequence visually.
165 Similarly, the mutations not found in the genome references used in the alignments
166 were considered New Mutations until they were not referenced in official media or
167 previous works. Subsequently, another matrix was used to create a heat map with
168 clustering showing the prevalence of each mutation against lineages from 0 to
169 100%.

170 DATA AVAILABILITY: Sequence data is available on the GISAID platform. All
171 other data is presented in the included tables and figures.

172 **RESULTS**

173 All patients that were included in this study lost their lives due to the COVID-19
174 infection or associated conditions. Out of 173 samples analyzed in the genetic
175 analysis, 150 were found to have sufficient quality for further examination and were
176 identified with SARS-CoV2 variants. Of these 150 results, 63 (42%) were identified
177 as delta variants and 87 (58%) as omicron variants. The characteristics,
178 symptoms, and comorbidities of the delta and omicron-infected patients are
179 presented in Table 1. The average age of the patients was 64 years, and there was
180 only a 3-year age difference between averages for the age of the omicron and

181 delta-infected patients. Male patients passed away more frequently than female
182 patients, with 66% and 34%, respectively, and this trend was observed in both
183 groups of variants.

184 The vaccinated population represented 27%, and further data is needed to
185 determine the effect on disease severity. Hypertension was the most common
186 comorbidity, present in 51% of the subjects, followed by diabetes mellitus at 38%.
187 Asthma was the pre-existing medical condition with the smallest number of cases,
188 occurring only in 3 subjects (2%).

189 An analysis was conducted to determine the duration between the onset of COVID-
190 19 symptoms and death among infected patients. The mean duration was found to
191 be 16 ± 10 days. However, patients infected with the omicron variant had a shorter
192 mean duration of 14 days, while patients infected with the delta variant had a
193 statistically significant more extended duration of hospitalization by an additional
194 four days ($p < 0.05$). All infected patients exhibited at least two symptoms.
195 Dyspnoea was the most frequent symptom reported by 90.6% of patients. Cough
196 was reported by 115 (76.6%) patients, with 54 and 61 patients infected by delta
197 and omicron variants, respectively, and had statistically significant ($p < 0.05$). Fever
198 was the most frequent complication reported (72.6%), followed by headaches and
199 diarrhea, with diarrhea being the least frequent (12.6%).

200 **Table 1. Demographic and clinical characteristics of study subjects.**

n (%)	Total (n=150)	Delta (n=63)	Omicron (n=87)	p-value

201 * The p-value is calculated from the Mann - Whitney test, and the ** p-value from the chi-square test.*** p-value is shown in
 202 Male cell, Gender was used as a categorical variable.

203 Over the three years of study, the evolution of the SARS-CoV2 virus was
 204 monitored for epidemiological surveillance in Aguascalientes. Genomic
 205 surveillance began in June 2021 and continued until May 2023 (Fig.1a). At the start
 206 of the study, the most prevalent lineages in the samples belonged to the delta
 207 variant (Table 2), with the AY.20 lineage having the highest number of deaths in
 208 the state. However, in early 2022, the prevalence of omicron lineages began to
 209 increase, with the B.1.1.529 lineages being the most prevalent. By early 2023, the
 210 XBB lineages occupied at least 50% of the COVID-19 cases and rapidly increased
 211 to 90% of the sequenced instances over the next few months. Despite this, the
 212 BA.1 (belonging to the omicron variant) and AY.3 (belonging to the o delta variant)

213 lineages were responsible for most of the recorded deaths, with 40 and 30 cases,
214 respectively (Fig. 1b).

215 **Figure 1.** Genomic data in Aguascalientes from June 2021 to May 2023. **a** Lineage
216 prevalence of SARS-CoV2. **b** Number of genomes sequenced from each
217 SARSCoV2 lineage. Lineages for less than one genome are collated into “Other
218 Lineage.”.

219 The analysis of alignments revealed mutations in all sequences compared to the
220 reference. Mutations present in at least 45% of the sequences were selected for
221 inspection. As expected, sequences identified in 2021 have fewer mutations than
222 those found in 2022 and 2023 (Figure 2). Nevertheless, some sequences
223 belonging to delta variants have more mutations than other sequences of the same
224 lineage (AY.3). Among all the mutations found, the spike protein has the most
225 mutations compared to other structural or non-structural viral proteins. However,
226 the most common mutation in most samples, except for five genomes, is T492I in
227 the nsp4 protein sequence. The mutations P323L for RNA-dependent RNA
228 polymerase (RdRP) and T485K for the spike protein are also present in most
229 sequenced genomes.

230 Additionally, we found two mutations not present in the reference sequences used
231 for different genomes or the control group, shown as New Mutations in Figure 2.
232 The first is L95M for the ORF 8 sequence, representing 31.33%, was found for the
233 first time in the sequence obtained in December 2021, is located in the C-terminal
234 end of the protein (Fig. 5b). The second is L46M for the ORF 9 sequence,

235 representing 22.66%, and appeared in a sample of January 2022, this sample
236 presented both mutations as most of the identified sequences located in the region
237 of interaction with human TOM70 (Fig 5c). Dyspnoea, cough, and hypertension
238 were the clinical data most common in patients whose specimens presented at
239 least one mutation.

240 Figure 2. Heat map of the presence and absence of mutations found in each
241 genome sequence of the 150 used. The lineage, year of detection, and mutation
242 sequence have different color codes for better identification. Likewise, the New
243 Mutations show a different color than the previously Reported Mutations.

244 The figure 3 shows the absence of these mutations in the control group of 443
245 sequences from all the states of Mexico, this behavior allows us to assume the
246 discovery of mutations associated with a population. They seem exclusively
247 present in the Aguascalientes state, making this a significant finding for the region.
248 However, further investigations are crucial to determine if these mutations exist in
249 other parts of Mexico. This discovery could have implications for our understanding
250 of genetic variations and their potential impact on human health.

251 **Figure 3.** Comparison of LOGO obtained from Multiple sequence alignment (MSA)
252 for ORF 8 and ORF9 sequences between the control and study groups. **a**
253 Schematic LOGO of MSA of the study group highlighting the L95M mutation site
254 for ORF 8 sequence. **b** Schematic LOGO of MSA of the control group highlighting
255 the absence of the L46M mutation for ORF 8 sequence. **c** Schematic LOGO of
256 MSA of the study group highlighting the L46M mutation site for ORF 9 sequence.

257 **d** Schematic LOGO of MSA of the control group highlighting the absence of the
258 L95M mutation for ORF 9 sequence.

259 As shown in Figure 4, the BA.5 lineage has all the mutations found, showing a
260 prevalence of at least 75% in the corresponding sequences of this lineage. The
261 new mutations have the highest prevalence in the lineages BA.1, BA.2, and BA.5,
262 reaching up to 75% in the corresponding sequences. On the other hand, lineages
263 AY.26, AY.43, and AY.20 have fewer mutations, with only four mutations in all
264 three cases. The mutation T492I for nsp4 is present in all lineages with 100%
265 frequency except for the AY.26 lineage, where it is present in only three genomes,
266 representing 37.5% of the sequences of this lineage.

267 **Figure 4.** Heat map of mutation prevalence (0 to 100%) in the genomes belonging
268 to lineages found in deaths reported in México between 2021 and 2023. The
269 mutation sequence and the New and Reported Mutations have different color
270 codes for better identification.

271 The mutation distribution (Figure 5) shows that most mutations are present in the
272 structural and accessory regions of SARS-CoV2. The Spike sequence, in
273 particular, has nine representative mutations out of the 150 genomes analyzed in
274 this study. The graphical genome is a general representation of the SARS-CoV2
275 genome structure that circulated in the center of México between 2021 and 2023.

276 **Figure 5.** Graphical representation of the SARS-CoV2 and overview of accessory
277 proteins with the new mutations. **a** Genome organization of SARS-CoV-2, the
278 nonstructural proteins are shown in green, the structural proteins are in red, and

279 the accessory proteins are in blue. The mutations are highlighted in their location,
 280 with the new ones colored red. **b** Schematic representation of ORF 8 protein with
 281 the L95M mutation site highlighted by the amino acid methionine. **c** Schematic

287 DISCUSSION

288 Mexico established a comprehensive epidemiological follow-up of the SARS-CoV-2
289 pandemic, carried out by various entities such as public health organizations,
290 academic institutions, and private entities. The collaborative efforts of these entities
291 underscore the significance of a multi-sectoral approach to tackling pandemics of
292 this nature [Hernández-Huerta et al. 2021, Taboada et al. 2021, Taboada et al.
293 2023]. The World Health Organization (WHO) has confirmed the presence of all
294 Variants of Concern (VOCs) in Mexico as of the latest reporting period. The timely
295 identification of VOCs is paramount for successfully implementing public health
296 measures and mitigating future outbreaks.

297 According to data from the INEGI (National Institute of Statistics, Geography, and
298 Information), the State of Aguascalientes has an area of 5,680 km², a population of
299 1.4 million inhabitants, and a population density of 265.2 habs/km², the
300 metropolitan area of the Aguascalientes City concentrates 81% of the total
301 population of the State, people over 60 years of age represent 10.3%. Which
302 undoubtedly represents a risk for the spread of the virus.

303 According to information from ENSANUT 2018 (National Public Health and
304 Nutrition Survey), abdominal obesity in Aguascalientes reaches up to 72.8% in the
305 adult population, with a prevalence of obesity of 32.6%, high blood pressure of
306 31.3%, and diabetes of 10.9%. % respectively. In addition, it has an incidence rate
307 of chronic kidney disease of 134.5 per 100,000 inhabitants. (Arreola-Guerra, et al,
308 2019) being factors that favor the severity of the disease.

309 The relationship between a host and a virus can be described as co-evolutive,
310 meaning that both entities evolve together over time. This relationship can
311 significantly impact the development of new virus variants, especially in
312 hospitalized patients. This is because when a virus infects a host, it adapts and
313 mutates to survive better and replicate within the host's body. The host's immune
314 system also evolves to combat the virus.

315 However, this co-evolutionary process can become problematic when a virus
316 mutates in a way that allows it to evade the host's immune system. This can result
317 in the development of new VOCs that are more infectious or virulent than the

318 original virus. This can be particularly dangerous in hospitalized patients, where the
319 immune system may weaken.

320 Therefore, it is essential to closely monitor the co-evolutionary relationship
321 between hosts and viruses, especially in healthcare settings. By doing so, we can
322 better understand the development of VOCs and take steps to prevent their spread
323 and minimize their impact on public health.

324 In Mexico, from 2020 to March 2022, 10% of COVID-19 patients required
325 hospitalization, and the lethality rate was less than 1% [García-López et al. 2022].
326 Hospitalized patients had a higher lethality rate of around 40%. Among these
327 hospitalized patients, around 1% required mechanical ventilation and had an even
328 higher lethality rate of around 80%. Analyzing patient demographics, age, and
329 patient type are crucial factors in COVID-19 outcomes in Mexico [Torres-Ibarra et
330 al., 2022]. Patients under the age of 65 who require hospitalization have a mortality
331 rate of less than 50%, which increases significantly with advancing age. Patients
332 aged 85 years or older have the highest mortality rate, reaching up to 60% [García-
333 López et al., 2022]. Connecting specific virus mutations to particular cases is
334 challenging due to their rarity.

335 However, the State Public Health Microbiology Laboratory (LESP) in
336 Aguascalientes has the advantage of having access to such valuable samples and
337 the ability to monitor the corresponding mutations in this particular population
338 continuously. This unique advantage allows for a comprehensive analysis of the

339 genetic variations of the virus. This analysis can significantly contribute to
340 understanding its regional evolution and spread.

341 This work focuses on molecular epidemiology and COVID-19-infected patient
342 demographics for all pneumonia-associated deaths in the Aguascalientes state
343 from the pandemic's beginning until May 2023. Aguascalientes is a small central
344 state situated in the Mexican Bajío region, serving as a connecting hub between
345 various large states in the center of the country, including San Luis Potosí,
346 Querétaro, Guanajuato, Zacatecas, and Nayarit due to its leading economic sector
347 being the manufacturing industry. The state is located in the Mexican Plateau,
348 which connects Mexico's Central and North regions. Previous country-wide
349 molecular epidemiology efforts have included this region, but only a few sequences
350 were analyzed compared to other states, such as the capital.

351 The CDC has reported that severe COVID-19 infection is more likely to occur in
352 patients with underlying chronic diseases, with 90% of hospitalized COVID-19
353 patients having at least one chronic condition. Hispanics, who have a higher
354 burden of chronic diseases such as obesity, diabetes, and renal disease, are at
355 greater risk for severe COVID-19 outcomes [Gil et al. 2020]. Worldwide,
356 comorbidities such as obesity and diabetes may be associated with a younger age
357 of severe disease in the Mexican population [Herrera-Esposito et al. 2022]. In
358 accordance, in the study group, the most prevalent co-morbidities were diabetes
359 and hypertension.

360 It is essential to consider that mortality rates are low in younger people, which we
361 also see here. The average age of the studied group is 64 years, significantly
362 higher than the publicly reported average age of 44 years in the Mexican
363 population. This is because older age is associated with worse health outcomes
364 and higher death rates for COVID-19 patients.

365 On average, in Mexico, it was previously reported that the delta variant infection
366 led to the highest maximum viral load and shortest time from symptom onset to
367 maximum viral load [Ribeiro et al., 2023]. There were similarities in the genomic
368 sequences of SARS-CoV-2 found in Mexico, Belize, and Guatemala in 2021, which
369 are associated with a highly infectious and virulent strain [Hernández-Huerta et al.
370 2021]. This demonstrates the rapid virus mutation rate during the pandemic's first
371 months to one year. Our results corroborate these findings and show that the
372 mutation rate has not slowed from 2021 to the end of 2023.

373 This study acknowledges that the aforementioned general aspects of the infection
374 apply to our data. The patient population had an average age of 64 years. The
375 mean age of patients infected with the Omicron variant was only three years
376 different from those infected with the Delta variant. Male patients exhibited a higher
377 mortality rate than female patients, with males accounting for two-thirds of the
378 analyzed population as compared to females.

379 This study could also confirm that children who are immunocompromised and
380 under the age of three who have contracted COVID-19 and have comorbidities,

381 particularly diabetes or obesity, are at a greater risk of developing pneumonia,
382 leading to death.

383 This study also confirms previous findings that BA.5 Omicron variant dominated
384 the fifth epidemic wave (summer 2022) in Mexico, replacing BA.1 and BA.2 and
385 that Aguascalientes was among the states with a transitory presence of BA.2 and a
386 low presence of BA.4 [Taboada et al. 2023, Castelán-Sánchez et al. 2023,
387 [García-López et al., 2023].

388 The most intriguing discovery involves the identification of two mutations that
389 appear to be associated with the population of Aguascalientes. Both proteins are
390 linked to immune system evasion [Zandi et al. 2022]. The first, L95M in ORF8, has
391 demonstrated a high mutation rate at amino acids 119 and 120, conferring
392 resistance to evasion. Nevertheless, this mutation is located in the region of
393 highest diversity found in North America and Oceania, despite not being previously
394 reported [Alkhansa et al. 2021]. On the other hand, ORF9 protein has shown
395 interaction with TOM70 (mitochondrial import receptor), reducing active IFN. The
396 L46M mutation is within the 11 amino acid residues that form the binding complex
397 with TOM70 [Gao et al. 2021], making it necessary to investigate whether it has a
398 more significant impact on this binding and, therefore, a more significant role in the
399 immune response. These findings open the door to analyzing the effects of these
400 mutations and their potential implications for viral infectivity, disease severity, or
401 clinical characteristics.

402 CONCLUSIONS

403 After evaluating patient demographics, virus evolution dynamics, and changes over
404 time, we identified unique characteristics of SARS-CoV-2 infection in patients
405 hospitalized for severe pneumonia in central Mexico during the pandemic. Our
406 findings revealed two new mutations specific to the lineages in this geographical
407 area. We also observed only two prevalent SARS-CoV-2 genomic lineages in
408 2023. Continuing genomic surveillance is crucial to detect emerging variants that
409 could potentially threaten public health. This study emphasizes the significance of
410 maintaining such vigilance to safeguard our communities. Understanding the
411 virus's genetic makeup and evolution patterns is essential for developing effective
412 vaccines and treatments.
